Received 2 June 2011; revised 11 July 2011; accepted 21 September 2011

The process of nanoparticle generation during nanosecond and picosecond laser ablation of various metals (Ni, Al, W, and stainless steel) in ambient air and argon gas was investigated. The number concentration of nanoparticles generated by laser ablation in argon gas was up to 100 times higher compared to that in ambient air. Three stable separate size peaks of nucleation, Aitken, and accumulation modes of nanoparticles were observed in case of argon gas, while in ambient air particles of a wide size spectrum (8–200 nm) were generated. The natural precursors in ambient air can have an effect on the size spectrum of particles composed of various chemical compounds with target material during the ablation process. The influence of laser process parameters and properties of investigated metals on the number concentration and size distribution of nanoparticles generated during ns- and ps-laser ablation was observed.

Keywords: nanoparticles, nanosecond and picosecond laser ablation, metals, size distribution, number concentration, ambient air, argon gas

1. Introduction

Comprehension of the aerosol formation as an inevitable process in laser micromachining technology is established and the application of laser ablation in production of nanoparticles is widely spread. However, characteristics of particles generated by laser ablation are not fully known. Therefore, the studies of particle concentration and their size distribution are hot topics in current laser ablation investigations recently [1–9]. Nanoparticle generation by laser ablation is used for a variety of applications such as biotechnology, electronic industry, etc. The laser ablation is also an intensive source of submicron particle generation and their possible leakage into ambient air, therefore investigations of the particle formation kinetics in ambient air during laser processing are essential for the evaluation of potential generation of particle emission and their impact on human health [7]. For example, during laser processing particles formed of metals (e.g., iron, aluminium), especially toxic (e.g., manganese, zinc) or carcinogenic substances (e.g., chromium (VI) compounds, nickel), might penetrate into a human organism and cause health concerns [8][9].

The physical process of particle generation begins with the absorption of laser irradiation in the beam/material interaction zone. Depending on the wavelength of the laser beam and the material properties, kinetic energy is transformed into thermal (in metals $10^{-13}$ s) [10], which cuts off chemical bonds in material. The phase transition occurs if the energy threshold for that material is reached. As a result, material can be melted, vaporized, or sublimated and the particle generation process begins.

Both the particle concentration and size distribution depend on laser operating parameters such as wavelength, pulse duration, energy, and repetition rate, beam scanning speed [3][7][10][11]. Studies show that experimental conditions during laser ablation could be established in order to control the particle size and distribution [1][3]. Besides, medium (ambient air, argon, water, etc.) in the ablation chamber also plays an important part in the particle formation process. It was experimentally estimated that the mass of generated nanoparticles in ambient air was up to 100 times higher than in water [3].

The aim of the study was to investigate the peculiarities of nanoparticle formation during laser ablation of different metals (nickel, aluminium, stainless steel, tungsten) and to characterize the difference of size distribution of the generated particles in respect of the laser irradiation type (nanosecond, picosecond) and medium in the ablation chamber (partially particle-free ambient air, argon gas).
2. Theoretical background

During the interaction of the laser beam and material, the light absorption is a general physical process \[ \text{Eq. (1)} \]. The energy coupled into material causes thermal heating, melting, and vaporization of material, plasma formation, and particle emission. In metals, free electrons interact with the intense electromagnetic irradiation. The energy is instantly absorbed by electrons and further distributed to the lattice. The laser pulse duration \( \tau_\ell \) is important for understanding what happens with the energy in the laser beam/material interaction zone. \( \tau_\ell = C_i/\gamma \) is the lattice heating time, \( \tau_e = C_e/\gamma \) is the electron cooling time, where \( C_e \) and \( C_i \) are electron and lattice thermal capacities, respectively, and \( \gamma \) is the electron–lattice coupling parameter specific to every material. Based on the two-temperature diffusion model by Chichkov et al. \[ 13 \], the laser beam/material interaction can be described by electron and lattice subsystem temperatures \( T_e \) and \( T_i \), respectively:

\[
C_e \frac{\partial T_e}{\partial t} = -\frac{\partial Q(z)}{\partial z} - \gamma(T_e - T_i) + S , \tag{1}
\]

\[
C_i \frac{\partial T_i}{\partial t} = \gamma(T_e - T_i) , \tag{2}
\]

where \( Q(z) \) is the heat flux, \( S \) is the heat source (laser pulse).

For picosecond pulses, condition \( \tau_e \ll \tau_L \ll \tau_i \) holds. The laser pulse duration is shorter than the lattice heating time. Particles from the material are removed partly by solid state–vapour transition and direct breaking of chemical bonds. For picosecond pulses (Eq. (1)) the electron temperature \( T_e \) becomes quasi-stationary:

\[
\frac{\partial}{\partial z} \left( k_e \frac{\partial T_e}{\partial z} \right) - \gamma(T_e - T_i) + I_a \alpha \exp(-\alpha z) = 0 , \tag{3}
\]

where \( k_e \) is the electron thermal conductivity, \( \alpha \) is the absorption coefficient, \( I_a \) is the laser intensity transmitted to the material, \( z \) is the depth of laser beam penetration into material perpendicular to the surface. In this case, lattice temperature \( T_i \) is

\[
T_i = \frac{I_a}{\gamma} \int_0^t \exp \left( -\frac{t - \theta}{\tau_i} \right) T_e(\theta) d\theta + T_0 , \tag{4}
\]

where \( T_0 \) is the initial electron temperature.

Taking this into account Eq. (4) can be simplified due to quasi-stationary condition of electron temperature:

\[
T_i \approx T_e \left[ 1 - \exp \left( -\frac{t}{\tau_i} \right) \right] \approx \frac{t}{\tau_i} T_e , \tag{5}
\]

where \( t \) is the time after the laser exposure. It means that electron cooling temperature \( T_e \) remains longer than lattice heating temperature \( T_i \) after exposure to picosecond laser pulses. Electron cooling temperature \( T_e \) at the end of the pulse is

\[
T_e \approx \frac{I_a \alpha}{\gamma} \exp(-\alpha z) , \tag{6}
\]

Lattice heating temperature \( T_i \) at the end of the laser pulse is

\[
T_i \approx \frac{F_a \alpha}{C_i} \exp(-\alpha z) , \tag{7}
\]

where \( F_a \) is the absorbed laser fluence, which is \( F_a = I_a \tau_L \). By using the condition of strong evaporation it can be described as

\[
F_a \geq F_{\text{th}} \exp(\alpha z) , \tag{8}
\]

where \( F_{\text{th}} \) is the threshold laser fluence for evaporation.

Equations (6)–(8) describe how laser intensity, material transmissivity, and thermal capacities influence the temperature of the electron and the lattice.

In the second case for nanosecond pulses, condition \( \tau_L \gg \tau_i \gg \tau_e \) holds. Equations (1),(2) for nanosecond pulses are:

\[
C_i \frac{\partial T_i}{\partial t} = \frac{\partial}{\partial z} \left( k_0 \frac{\partial T_i}{\partial z} \right) + I_a \alpha \exp(-\alpha z) , \tag{9}
\]

where \( k_0 \) is the conventional equilibrium thermal conductivity of the metal and \( T \) represents general temperature of the subsystem because in case of ns-laser ablation \( T_e = T_i = T \).

The energy absorbed by electrons is fully transferred to the lattice during the laser pulse duration. Material is heated due to the absorbed energy of the lattice. In this case, solid material melts, the beam/material interaction zone spreads and particles are evaporated from liquid state. Metals have good thermal conductivity properties, thus increasing the energy loss due to the lattice heating for nanosecond pulses.

3. Experimental set-up

The experimental set-up is schematically shown in Fig. 1. The main parts are: the laser, the galvoscanner for the laser beam control and an ablation chamber,
Fig. 1. Experimental set-up for generated particle measurement.

Fig. 2. Particle size $d_p$ distribution for the ns-laser ablation of nickel in ambient air at 0.4 W, 10 kHz, 200 mm/s, and 40 kHz, and the beam scanning speed 10–1000 mm/s. Those of the picosecond laser: the average power 0.1–2 W, the pulse repetition rate 50 kHz or 100 kHz, and the beam scanning speed 10–1000 mm/s. For data analysis of the size distribution of generated particles by laser ablation in ambient air the Aitken classification of atmospheric aerosol particle modes was used [16].

4. Results

Samples were placed into the chamber and it was filled with the operating gas. The laser beam was scanned over the sample surface and both techniques were applied to measure the particles in the exhaust gases. During the experiments the particle size distribution was averaged from 3 to 8 measurements. The geometric mean of the particle size diameter $d_p$ and the standard deviation $\sigma_g$ were calculated. Solid curves in
Fig. 3. Particle size $d_p$ distribution for the ps-laser ablation in ambient air: (a) nickel at 0.25 W, 100 kHz, 10 mm/s, and 0.80 J/cm$^2$; (b) aluminium at 0.6 W, 50 kHz, 10 mm/s, and 3.82 J/cm$^2$; (c) tungsten at 0.25 W, 100 kHz, 1000 mm/s, and 0.80 J/cm$^2$.

Figs. 2, 3, 5 were obtained by fitting the data using DistFit program [17].

**Nickel.** Particle generation data by ps- and ns-laser ablation of nickel in ambient air are shown in Figs. 2 and 3. As seen, the processes involved in particle formation were partially different. Smallest particles of 8 nm size (nucleation mode) with the concentration up to $5 \cdot 10^4$ cm$^{-3}$ were observed in the case of the ps-laser. Particles generated in the nucleation mode with the size of 18 nm and with three times higher number concentration were observed during ns-laser ablation as well (see Table 1). However, in the case of the ns-laser ablation, a wide size spectrum of particles from 10 to 180 nm with a sharp peak only in the nucleation mode was observed (Fig. 2). CPC data showed a growth of the particle number concentration in time during the laser ablation (Fig. 4(a)).

Sharp peaks of the nucleation, Aitken, and accumulation modes at 8, 57, and 164 nm, respectively, were observed in the particle size distribution during the ps-laser ablation (Fig. 3(a)). Particle number concentrations of these modes were $(5.0 \pm 0.2) \cdot 10^4$, $(1.6 \pm 0.15) \cdot 10^4$, and $(6.2 \pm 0.15) \cdot 10^4$ cm$^{-3}$, respectively. The CPC data show an intensive particle generation process in the first minutes and a slow declining tendency in time using a different laser beam scanning speed (Fig. 4(b)). The highest nickel particle concentration (up to $1.2 \cdot 10^5$ cm$^{-3}$) was generated in ambient air using the ns-laser (Table 1).

Generation of particles was also performed in the argon gas flow. It was observed that generated nickel particles using both types of lasers had a narrow size distribution peaked at 20 nm with the high number concentration $(1.4 \cdot 10^6$ cm$^{-3}$) and the concentration lower by order of magnitude at 107 nm $(2.0 \cdot 10^5$ cm$^{-3}$) using the ns-laser and at 8 nm $(1.8 \cdot 10^5$ cm$^{-3}$), at 46 nm $(5.9 \cdot 10^5$ cm$^{-3}$) and at 166 nm $(2.9 \cdot 10^5$ cm$^{-3}$) using the ps-laser ablation (Table 1). Generation of nickel particles by ps-laser ablation, as can be seen in Fig. 5(a, d), was weaker compared to the ns-laser ablation and caused a shift of the size distribution peak from 20 to 46 nm and to a coarse particle range (166 nm).

**Aluminium.** Generation of aluminium particles by the ps-laser ablation in ambient air was inefficient. As seen in Fig. 3(b), generated particles were of nucleation and Aitken modes. The highest number concentration of generated particles was in the nucleation mode at 20 nm $(1.6 \cdot 10^5$ cm$^{-3}$) (Table 1). CPC data showed a rapid sink trend of the particle number concentrations in time (Fig. 4(e)).

The opposite situation was observed in the case of the aluminium particle generation in argon gas using the ns-laser compared to the ps-laser. The largest number concentration of particles was in the nucleation mode at 20 nm $(1.6 \cdot 10^5$ cm$^{-3}$) (Table 1). CPC data showed a rapid sink trend of the particle number concentrations in time (Fig. 4(e)).
Table 1. Maximum number concentration of generated particles during nanosecond (ns) and picosecond (ps) laser ablation in different media, cm$^{-3}$.

and 99 nm (Fig. 5(b)). The maximum particle number concentration reached 1.13$\cdot$10$^6$ cm$^{-3}$ for the smallest size of 21 nm (Table 1).

The measurement data showed that the maximum number concentration of generated aluminium particles by the ps-laser was (1.7–2.5)$\cdot$10$^5$ cm$^{-3}$ and it was higher than in the case of the ns-laser, i.e. the particle size ranged widely from 50 to 200 nm with two maximums: at 79 and 170 nm (Fig. 5(e), Table 1).

**Tungsten.** Generation of tungsten particles by laser ablation was investigated using only the ps-laser in ambient air and argon gas medium. The size distribution of generated particles was completely different in both cases and evidently showed that the particle size distribution strongly depended on the experimental conditions. The highest number concentration (3.9$\cdot$10$^5$ cm$^{-3}$) was found during the ps-laser ablation in argon gas and the particle size distribution in this case was observed in a wide range from 18 to 200 nm (Table 1). In both media, particles of a narrow size mode were not formed, but a wide size spectrum was observed with a shift to the smaller particle size in ambient air, while in argon gas it was shifted to the coarse particle size (Figs. 3(c) and 5(f)). Measurement in argon gas showed two number concentration peaks at 36 and 131 nm. CPC data of tungsten particle formation are shown in Fig. 4(c, d) during the ns- and the ps-laser ablation. As seen, the dynamics of the generated particle number concentration shows that during ablation in ambient air and argon gas the production of particles was different.

In the case of tungsten CPC data showed a slight growth of the particle number concentration for the ns-laser ablation whereas a small declining tendency in the first six minutes for the ps-laser ablation and a further slow growth of the particle number concentration were observed (Fig. 4(d)).

**Stainless steel.** The experimental data on generation of particles in stainless steel by the nanosecond laser ablation in argon gas are shown in Fig. 5(c). It should be noted that the particle number concentration reached 1.86$\cdot$10$^6$ cm$^{-3}$ (the distinct peak at 17 nm), but the size spectrum of generated particles was ranging to 200 nm.

The second small peak at 190 nm in the size distribution of generated particles was observed.

5. Discussion

In this research, as in many cases of such type of investigations [3, 5, 10, 11, 18–20], it has been shown that concentration of generated particles and their size distribution depend on the experimental medium, target material properties, and laser process parameters. At first, the formation of nanoparticles and their size were affected by parameters of laser irradiation – the intensity, pulse length, and radiation wavelength. Our experimental data showed that the smallest (∼8 nm) particles of nucleation mode were formed by the picosecond laser ablation (Figs. 3 and 5). Larger (17–21 nm) particles of nucleation mode were generated during the nanosecond laser ablation.

Different physical mechanisms of the laser beam/matter interaction for ns- and ps-lasers have an effect on the diameter of generated particles. The primary thermal nature of nanosecond laser ablation can lead to formation of a molten layer and ejection of melted particles at evaporation, in addition to particles formed from condensation [1]. The metal surface impacted by picosecond laser radiation can be attributed to electrons and mass emitted from the target surface, while particle generation after several 10 ns pulses proceeds due to emission of particles and droplets after a thermal boiling process. Vaporized material, in contact with metal, is ionized and over the target surface a formation of plasma cloud from electrons, ions, and particles of metals starts [5, 11, 19, 21]. Our registered smallest nickel particles of nucleation mode (∼8 nm) by the ps-laser ablation can be produced during this process (Figs. 3 and 5).

Experimental results have shown that the generated particles (nickel, aluminium) during the ps-laser ablation are characterized by the maximum in the particle size range of 160–170 nm, while during the ns-laser ablation particles of size range of 90–110 nm were produced (Table 1).

The effects of various laser process parameters on the nickel particle size and number concentration during the nanosecond laser ablation in argon gas at four different laser intensities were observed, and two almost identical narrow peaks of size distribution of particles for all energies were obtained (Fig. 6(a)). Two narrow peaks of nickel particles in the range of 14–18 nm and 100–150 nm at pulse energies from 90 to 207 µJ were observed. It should be noted that by changing the laser beam scanning speed (10 or 100 mm/s) the difference in the particle concentration and size distribution was very small.

The same results were observed in experiments with aluminium (Fig. 6(b)). Two narrow peaks of particles in the range of 20–24 nm and 80 nm at laser pulse energies from 47 to 89 µJ with stable particle
number concentration by changing the laser beam scanning speed (100 or 1000 mm/s) were obtained. The production of the maximum number concentration of metal particles by laser ablation in argon was reached: for nickel at 93 µJ, stainless steel at 350 µJ, and aluminium at 89 µJ.

As seen in Fig. 6(c), the largest effect on stainless steel particle generation at various (150–385 µJ) ns-laser pulse energies was observed at 350 µJ pulse energy and the beam scanning speed of 10 mm/s.

The variations of the nickel particle number concentration only of the smallest size particles (10–12 nm) during the ps-laser ablation in argon gas by changing the laser beam scanning speed (100 or 1000 mm/s) were observed. In case of stainless steel during the ns-laser ablation by changing the beam scanning speed from 10 to 100 mm/s, the particle number concentration varied about two times in the range of 14–18 nm. The optimal regime for particle generation (nickel and stainless steel) was observed at the following laser parameters: the pulse frequency 10 kHz and the beam scanning speed 100 mm/s.

As seen in Figs. 2, 3, and 5, the size distribution and number concentration of generated metal particles during laser ablation in ambient air differed from those in argon gas. First of all, we consider that formation of particle size and their number concentration was influenced by the complex of precursors (oxygen, water vapour, suspended matter <5 nm, etc.) present in ambient air, which was passing through the ablation chamber. Precursors themselves are actively forming various chemical compounds with generated metal particles (NiO, Al₂O₃, FeO) during the ablation. Studies of particle formation by Gonzalez et al. [1] show that the particle size strongly depends on the precursor concentration (atoms and clusters), which will affect the size of the primary particles. The oxidation process of nickel particles during laser ablation in ambient air is shown in works of Liu et al. [5]. For example, in Fig. 2 it can be seen that the nickel particle size spectrum is wide and the generation of particles by the ns-laser in narrow ranges was not observed. The standard deviation of the generated particle number concentration at 61 nm was σ₉ = 3.21 and only a sharp peak of smallest nickel particles at 18 nm (σ₉ = 1.15) was observed.

Investigation of the nickel particle formation by the ns- and ps-laser ablation in ambient air showed that the influence of precursors on the particle size and concentration was different as well. The size distribution of the generated nickel particles showed that during the ps-laser ablation in argon gas the smallest particles in the nucleation mode (dₚ = 8 nm) and coarser particles in Aitken (dₚ = 46 nm) and accumulation (dₚ = 166 nm) modes were produced (Fig. 5(d)). The standard deviations of the particle concentration for these sizes were σ₉ = 1.35, σ₉ = 1.13, and σ₉ = 1.56, respectively. In addition to the particle size in the range from 10 to 100 nm for nickel during ps-laser ablation in ambient air the influence of precursors was observed, except for particles less than 8 nm with σ₉ = 1.37 (Fig. 3(a)). Comparison of the aluminium particle size with the size of nickel and tungsten particles under the same ablation conditions (ambient air, ps-laser) showed a wide variety range of all particles (Fig. 3). Aluminium particles in a wide range with peaks at 20 nm (the standard deviation σ₉ = 1.31) and with a negligible peak at 43 nm (σ₉ = 2.32) were formed (Fig. 3(b)). Based on aluminium properties, it is possible to explain that the ablated particles can be originated from Al₂O₃. A constant film of aluminium oxide is formed on the surface of this metal in contact with air [10].

Besides, the influence of precursors during the picosecond laser ablation in ambient air was observed in case of generated tungsten particles. As seen in Fig. 3(c), Aitken mode particles dominated (dₚ = 31 nm, σ₉ = 2.46) in a wide size spectrum. The accumulation mode was clearly distinguished in the particle size distribution (dₚ = 186 nm, σ₉ = 1.13). In general, the particle generation of all investigated metals in ambient air was very small.

Experimental data of particle formation by the ns- and ps-laser ablation in argon gas have shown that the particle size distribution and concentration depended on the processed metal characteristics, on the laser process parameters as well as on the thermodynamic conditions in the processed zone. For example, during the ns-laser ablation in argon gas smaller particles were produced (17–21 nm) than during the ps-laser ablation, except for nickel particles (dₚ = 8 nm, σ₉ = 1.35) (Table 1, Fig. 5(a, d)).

Furthermore, the dependence of the nanoparticle size distribution on material properties of various metals during the ns- or ps-laser ablation was observed. The laser pulse energy influencing the size distribution of nanoparticles generated during laser ablation of various materials depends on their reflectivity [10]. The smallest particles are generated at higher pulse energies, but a size shift decreases for materials with lower reflectivity.

Our measurement data showed that during the ns-laser ablation of stainless steel, nickel, and aluminium the shift to a smaller size range was observed at higher

pulse energy in metals with lower reflectivity. We observed the smallest generated particles ($d_p = 17$ nm) of stainless steel (34% reflectivity) at 350 µJ pulse energy whereas aluminium (91% reflectivity) generated particles were of 21 nm size at 89 µJ pulse energy (Fig. 6, Table 2).

The explanation for separate number concentrations of nanoparticles and their size spectrum of investigated metals is more complicated due to the different physical properties of each material. As can be seen in Fig. 5, a major variety of discrepancy of modes of produced particles among metals is observed during the picosecond laser ablation. Our results for tungsten are in agreement with [22] where an increase in the formation of larger particles of elements with a high melting point was determined. As seen in Table 2, the melting point of tungsten is highest among investigated metals, and a wide size spectrum of generated tungsten particles with a shift to the coarse particle size compared to other metals was observed (Fig. 5).

According to the investigations by Gonzalez et al. [1], Brikas [10], and Hola et al. [22], the influence of material properties on the size and concentration of particles generated by the nanosecond laser ablation is important. The higher number concentration of stainless steel and nickel particles produced by the ns-laser (Table 1) could be related to the lowest thermal conductivity of these metals compared with other investigated metals (Table 2). Generally, the generation of stainless steel, nickel, and aluminium particles by the ns-laser ablation in argon gas was the most intensive.

6. Conclusion

The peculiarities of nanoparticle formation during the ns- and ps-lasers ablation of nickel, aluminium, stainless steel, and tungsten in ambient air and argon gas were investigated experimentally.

It was found that the size distribution and number concentration of generated metal particles during the laser ablation in ambient air differed from those in argon gas medium. The number concentrations of generated nanoparticles during the laser ablation in argon gas, compared to the produced nanoparticle concentrations in ambient air, were up to 100 times higher and characterized by separate stable size peaks (nucleation, Aitken, and accumulation modes) of nanoparticles, while a wide size spectrum (from 8 to 200 nm) of generated nanoparticles without clear separation of the size modes in ambient air was observed. The natural precursors in ambient air can have an effect on the size spectrum of particles composed of various chemical compounds with target material during ablation process.

Primary particles of 8 nm size during the ps-laser ablation and of 17–21 nm size in nucleation mode by the ns-laser ablation were produced. It was evidently caused by different physical processes in the laser beam/material interaction zone.

The influence of laser process parameters on the number concentration and a shift in dynamics of size distribution of nanoparticles generated during the ns- and ps-laser ablation in argon gas were observed. The maximum number concentration of generated metal particles by laser ablation in argon was reached: for nickel at 93 µJ, stainless steel at 350 µJ, and aluminium at 89 µJ. Moreover, the dependence of the investigated metal properties (reflectivity, melting point, and thermal conductivity) on the size distribution and number concentration of generated nanoparticles was determined.

The study showed that according to particular laser process parameters during the nanosecond and picosecond laser ablation in argon gas the generation of stable separate modes of nickel and aluminium particle size distribution can be controlled.

Further investigations will focus on the development of technology of generation of monodisperse metal nanoparticles (the standard deviation $\sigma_g = 1.1$) based on primary and secondary particle formation physical processes.
